SUMMARY

In low-incidence countries, tuberculosis (TB) is now largely concentrated in high-risk groups such as migrants, homeless people, illicit drug users, alcoholics and prisoners. This has led to increased efforts to implement targeted active case finding for TB among specific populations. This review examines the evidence supporting active case finding in migrants and social risk groups, as well as the cost-effectiveness of interventions. While data from observational studies support active case finding in defined high-risk groups, further research to determine the effectiveness of specific tools and the cost-effectiveness of screening strategies is needed to inform evidence-based control methods in low-incidence countries. Inevitably, addressing TB in low-incidence countries will depend on effective disease control in high-burden countries.

KEY WORDS: low-incidence countries; tuberculosis; active case finding; migrants; homelessness

GLOBAL TUBERCULOSIS (TB) control efforts, underpinned by the World Health Organization (WHO) Stop TB strategy,1 have focused on improving case detection and treatment completion, for example through the introduction of directly observed treatment (DOT), to reduce transmission and to limit the development of anti-tuberculosis drug resistance. The majority of cases are identified through passive case finding following the presentation of a symptomatic TB patient to health services.2 TB control strategies in low-incidence countries have undergone considerable changes over the last 50 years. In response to declining rates, many countries reduced their investment in TB control, which was often followed by a resurgence of TB in some population groups. This phenomenon requires renewed efforts to contain a more complex epidemic, including various forms of active case finding (ACF).3

ACF, defined as a strategy to identify and treat people with TB disease who would otherwise not have sought prompt medical care,2 was initially widely implemented in the early part of the twentieth century. Probably best known are the efforts to screen whole populations for active pulmonary TB (PTB) with mass radiography,1,2 which was one of the pillars of the ‘vertical approach’ of control in many Western countries.1 As ACF is usually very resource intensive, not surprisingly, mass radiography was stopped in countries where the yield had declined with falling incidence. ACF that uses contact investigations around infectious cases, however, continues in most Western countries, even during periods of very low levels of TB. As the introduction of these interventions pre-dated the rise of evidence-based medicine, there have been limited opportunities to subject them to rigorous evaluation.4

In low-incidence countries, TB is concentrated in specific subpopulations, usually in major urban centres. Risk factors are often linked to migration from a high-incidence area, lifestyle (e.g., homelessness, illicit drug use or alcoholism) or imprisonment, and can also be related to underlying illnesses. TB incidence rates in these groups often dramatically exceed background incidence, for example as the result of within-group transmission among homeless persons or drug users. Conversely, engagement with health services is often more difficult in some risk groups compared with that in the general population, resulting in delayed diagnosis, onward transmission, poor treatment adherence and a consequent disproportionate contribution of these population groups to the TB burden. This situation has prompted the United Kingdom’s National Institute for Health and Clinical Excellence (NICE) to issue specific guidance for ‘hard-to-reach’ groups. This article reviews and summarises the published literature about ACF activities among high-risk groups in low-incidence countries and the effectiveness of these approaches to inform future TB control strategies in these settings. Tables 1 and 2 outline the methodology and definitions used in the review.

**Diagnostic tools for active case finding in low-incidence countries**

ACF is usually focused on the early detection of PTB and is sometimes limited to smear-positive disease, as these patients are deemed more infectious. Common screening tools for ACF in low-incidence settings include tests such as a symptom enquiry (often as a standardised symptom questionnaire), and chest X-rays (CXR), used separately or in combination. Further diagnostic tools include sputum smears or cultures and molecular tests such as Xpert® MTB/RIF (Cepheid, Sunnyvale, CA, USA). The test properties for some of these tools, including diagnostic accuracy and inter-reader agreement for radiography, are dependent on the background prevalence of TB in the screened population and setting.

There are very limited published data on symptom screening in low-incidence settings. Standard items on symptom questionnaires are cough lasting more than 2–3 weeks, haemoptysis, fever, weight loss and night sweats. Considered separately, each of these symptoms has a low specificity for PTB. However, observational studies from high-burden settings suggest that where these symptoms are combined, for example by enquiring about ‘any symptom’, they show moderate to high sensitivity (65–90%), albeit with low to moderate specificity (30–68%) to detect microbiologically confirmed TB. The sensitivity of symptom enquiry may be improved through the use of standardised questions and scoring systems, but this often leads to low specificity. In addition, ACF should ideally detect TB early, before the symptoms become obvious. Among hard-to-reach groups, such as illicit drug users, symptoms may be difficult to interpret, given that the individuals may have a chronic cough or weight loss for other reasons. Symptom enquiry on its own is therefore unlikely to be helpful for ACF among some high-risk groups in low-incidence countries. In practice, symptom questionnaires are often combined with other case-finding tools.

In low-incidence countries, radiological screening for TB targeting specific high-risk groups has re-emerged as a viable approach. Digital CXR technology makes it easier to conduct ACF among risk groups with good test properties and reasonable inter-reader agreement. Recent observational data have suggested that the sensitivity and specificity of digital CXR screening for active disease in these settings can be as high as 82% and 99%, respectively. CXR test properties depend on the presence of typical radiological features (which may be absent or difficult to identify
in early disease and in immunocompromised individuals), the quality of the X-ray film, the skills of the reader and the background TB prevalence in the population screened. CXR screening will not identify extra-thoracic presentations of TB. Based on observational studies in low-incidence countries, reported levels of CXR sensitivity and specificity range between 59% and 82% and 52% and 99%, respectively.25-27

Patients’ sputum may be obtained during ACF, usually following a positive result from either a symptom questionnaire or CXR. The sputum is examined using Ziehl-Neelsen or auramine-based stains (‘sputum smear’) to detect acid-fast bacilli. Population-level data on smear-based screening among high-risk groups in low-incidence countries are lacking. Although cases with a positive smear are more infectious, outbreaks due to transmission from smear-negative PTB have occasionally been reported, with molecular epidemiological studies estimating that 10–20% of all transmission arises from such cases.28-31 The predictive value of sputum smears depends on the prevalence of TB in the screened population, the quality of the sample collection, the number of smears taken and overall quality control.32

Mycobacterial culture (e.g., on Löwenstein-Jensen slopes or liquid media) is very sensitive and remains the diagnostic standard for TB.16 However, its use for case-finding exercises is limited by the length of time needed for bacterial growth. The use of liquid media improves diagnosis by reducing the time to a positive culture, with moderate to high recovery rates (74–97.8%) varying according to the study and the system used.34

Commercially available rapid nucleic acid amplification assays based on the amplification of DNA fragments from mycobacteria have a reasonably high sensitivity (86–97%) and specificity (83–99%) on smear-positive and -negative specimens.16 However, their use for ACF has been limited by their relatively high cost. The WHO recently endorsed two molecular approaches to test for TB: line-probe assays (LPA) and Xpert MTB/RIF.35 LPAs, based on the targeted amplification of specific parts of the M. tuberculosis genome, have become widely available, and the DNA amplification is automated in this diagnostic system. They are rapid, simple to use and have a high sensitivity and specificity (pooled estimates 93% and 83%, respectively) for diagnosing PTB and various drug resistances.36,37 Xpert MTB/RIF, another molecular assay, has pooled sensitivities of around 98% (95% confidence interval [CI] 98–99) and 75% (95% CI 72–78) for smear-positive and smear-negative sputum samples, respectively, whereas specificities were given as 99% (95% CI 99–99%) for both smear-positive and smear-negative samples.38 Globally, Xpert appears to be cost-effective for diagnosing multidrug-resistant TB.39 However, if used as a screening test for ACF programmes in low-incidence countries, the high cost of these tests would in all likelihood render them non-cost-effective.

Targeting the delivery of active case finding
In low-incidence areas, potential risk groups for ACF include contacts of (P)TB cases, migrants and asylum seekers,9 indigenous populations with a high incidence of TB, drug users, homeless persons and asylum seekers, as well as persons in high-risk occupational settings, such as staff in health care or elderly care, patients and staff in psychiatric facilities, and patients with co-morbidities, as well as those who have tested positive for the human immunodeficiency virus (HIV; Table 3). A separate group, not discussed here, is made up of patients in advance of planned immunosuppression, such as solid organ recipients or candidates for tumour necrosis factor alpha blocking medication (‘biologicals’).40 Apart from established public health practices, such as screening contacts of infectious index cases, and legal requirements, such as migrant screening in many low-incidence countries, the relative importance and burden of disease in other risk groups is setting-specific. Ultimately, the decision to screen specific groups should be based on a needs assessment, taking into account the disease burden, the level of transmission, access to health care, the cost-effectiveness of interventions and opportunity costs, and should be complemented by tailored opportunities for completion of the diagnostic process and treatment.

Contact investigation usually aims to detect individuals with latent TB infection (LTBI), especially in people at high risk of progressing to active disease or early TB disease (Figure). While contact investigation is a recognised approach for ACF, previous reviews and guidelines have comprehensively addressed its role.41,42 More evidence is needed to support this well-established strategy.43,44

The concentration of TB in particular high-risk groups inevitably means that coordinated efforts to
implement ACF in low-incidence areas are focused on migrants from high-incidence areas and other risk groups, such as homeless people, prisoners and drug users. This article therefore focuses on these risk groups in particular.

**Migrants**

The screening of migrants from countries with a high incidence of TB is well established in many low-incidence areas. The screening tools used, the screening sites and the subgroups of migrants targeted differ substantially between countries. For example, a recent survey by Pareek et al., showed considerable variations in the approaches used by member states of the Organisation for Economic Co-operation and Development. Several other large surveys have been conducted to review the type and efficacy of case finding initiatives, both globally and in Europe. Migrant screening can take place before entry (pre-departure screening), at entry (on-arrival or port-of-entry screening) or after arrival (post-entry screening).

The effectiveness of migrant screening, usually assessed through screening yield and sometimes coverage, is influenced by the rates of TB in the country of origin of the new entrants, the conditions of migration (infection acquired pre-entry) and the migrants’ subsequent travel back to those countries (infection acquired post-entry) and the migrants’ infection rate in the country of entry. Furthermore, living conditions among migrants in low-incidence countries, in particular those living in deprived, overcrowded settings, may lead to post-entry transmission of infection between migrants.

In line with the objective to find and treat the most infectious cases, CXR screening is used most frequently and, if positive, is usually followed by further investigations, such as sputum smears and culture confirmation. Occasionally, CXR screening is preceded by a symptom enquiry. Some countries, such as the United States and Australia, use CXRs to follow up inactive forms of TB, usually organised as post-entry screening within the host country. Migrant ACF is also combined with LTBI screening in some countries.

Almost all current new migrant ACF programmes are centrally organised, but implementation is often decentralised. In some countries, the requirement to comply with TB screening is linked to migrants’ rights and responsibilities, such as when there is an obligation for TB health clearance screening as a condition for obtaining a residence visa, as is the case for Australia, the Netherlands, Switzerland, Norway and the USA. Asylum seekers and refugees, who are recognised as having a high risk of TB even among migrants, are often targeted as a high priority group for screening.

The overall median yield of any migrant screening in the European Union (EU) was estimated at 0.35% (interquartile range [IQR] 0.11–0.71), but the yield was lower when only studies from large, national programmes were included (0.18% [IQR 0.11–0.33]). Non-EU studies had a slightly higher, but comparable yield (0.51%, IQR 0.17–1.23). In studies published after 2008, we also found a comparable

---

**Figure** Conceptual model based on the natural history of TB illustrating opportunities for active case finding. TB = tuberculosis; TST = tuberculin skin test; IGRA = interferon gamma release assay; LTBI = latent tuberculosis infection; HIV = human immunodeficiency virus; TNF = tumour necrosis factor; CXR = chest X-ray.
yield (median 0.31%, IQR 0.26–0.61, Appendix Table A.1). Alvarez et al. found a lower overall yield (0.11%, IQR 0.08–0.15). However, coverage is highly variable by setting, with Klinkenberg et al. reporting a range of between <20% and 100%, although most national programmes had higher coverage (>90%). Mandatory programmes had a higher median coverage than voluntary programmes (90.6% vs. 48.5%).

Pre-entry screening is currently used by the USA, Australia, Canada, New Zealand and the United Kingdom, with migrants required to obtain a TB health clearance certificate from a designated centre in their country of origin; in the event of positive findings, treatment completion may be required. The costs for obtaining this are usually borne by the individual. Pre-entry programmes are therefore attractive to the host countries and, where they are supported by an effective quality assurance programme, can improve the early detection of cases. A retrospective observational study from the USA suggested that pre-entry screening with CXR, combined with smears and culture, was associated with a reduction in TB occurring among migrants within 6 months of arrival. In another observational study, the Israeli screening programme in Ethiopia was also shown to reduce the risk of TB among migrants screened overseas compared to those screened after arrival. A Canadian descriptive study identified limitations of the pre-entry screening programme and suggested strengthening LTBI detection among high-risk migrants after arrival. The median yield of pre-entry screening programmes was estimated to be higher than other forms of migrant screening (1.21%, IQR 0.85–1.25), an observation also shared by Mor et al. in their analysis before and after the introduction of their pre-entry screening programme in Israel.

Several countries have an on-arrival screening system using CXR and symptom enquiry, usually at ports of entry, with subsequent follow-up within the country administered and funded by the host country itself. This system has inherent problems, including its cost, relatively low case yield, estimated at 0.18% (IQR 0.09–0.35), and difficulties with seamless integration into national health services for further follow-up. Coverage was estimated at 92.4%.

A number of countries have centrally organised ACF systems for new migrants after arrival. Service models vary, and include screening in transit centres or referral to Municipal Health Services (the Netherlands). In some countries, such as Australia, post-entry systems are used to follow up individuals who have been found to be at a higher risk of TB (e.g., with non-specific CXR changes pre-entry) or to organise LTBI screening. National post-entry screening programmes inside and outside the EU achieved a yield of 0.3%. We found a slightly higher yield of post-entry screening in more recent studies (0.42%, IQR 0.31–0.62, Appendix Table A.2).

Several authors have examined the costs and cost-effectiveness of various migrant screening models. Migrant screening at entry was not found to be cost-effective and had little impact on overall TB trends. Targeting post-entry LTBI screening at migrants from countries with an incidence of TB exceeding 150 per 100 000 population was found to be cost-effective.

Further research into the potential impact of integrating LTBI screening into ACF activities on the epidemiology of low-incidence countries and into its cost-effectiveness would be beneficial. In addition, questions about the impact of migrant screening on host-country epidemiology remain, and few studies present data other than yield and coverage. Several studies have reported numbers of ‘missed cases’ (e.g., TB cases arising from the screened ‘TB-free’ cohort). One study presented ecological evidence that the incidence of TB in countries with migrant screening programmes was lower than in those without such a programme, but these findings are difficult to interpret, as the direction of association is unclear, and there is considerable potential for inter- and intra-country confounding. There is therefore a need for robustly designed studies to estimate the impact of migrant screening on the host country’s epidemiology. Any screening should ideally be delivered as part of a package of care to migrants that includes support for other health needs.

Social risk groups

The incidence of TB among homeless persons, illicit drug users, alcohol misusers or prisoners substantially exceeds the background rates in many low-incidence countries. To administer and evaluate ACF initiatives among these groups, it is necessary to define those who are eligible and implement an effective outreach strategy—a process that can be complex and challenging. ACF can be initiated by local public health services. Organisations with experience of working with these groups, often from the voluntary sector or civil society, are well placed to facilitate such initiatives. Compared with large, centrally organised migrant screening programmes, many ACF activities in these risk groups are small-scale and more local.

Despite the large number of initiatives, few have been evaluated and published. Appendix Table A.2

\*The Appendix is available in the online version of this article at http://www.ingentaconnect.com/content/iuatld/ijtld/2013/00000017/00000005/art00004
(A and B) shows those ACF initiatives among homeless persons, illicit drug users, alcohol misusers and prisoners in low-incidence countries, where clear outcome information was available. The majority (17/27) of these studies describe ACF among homeless populations. CXR-based case finding is the most common approach, often supported by symptom enquiry and further investigations as required (e.g., sputum smears). Common settings for voluntary screening are shelters. Although voluntary screening dominates the method of delivery, some programmes tried to link ACF or TB screening to shelter admission and associated benefits. Most ACFs specifically target PTB, but some programmes screen for LTBI, either alone or in conjunction with PTB. A mobile X-ray unit has been used successfully to facilitate ACF in Rotterdam, Paris and London among homeless persons, prisoners, illicit drug users and asylum seekers.

The size and yield of the programmes aimed at homeless persons was highly variable (Appendix Table A.2A). Programmes screened between 120 and 22,000 homeless people (median 726), and detected 0–313 cases of active TB (median 9.5). For programmes where information on the screened population and yield was available (n = 14), the case yield ranged between 0% and 6%, highlighting the importance of targeting the intervention appropriately. The most robust evidence of effectiveness was shown by assessing secular trends in recognised molecular clusters in Rotterdam, with evidence of decline of a proxy indicator of recent transmission after introduction of systematic mobile digital CXR screening among illicit drug users and homeless persons. This study demonstrated the potential for population-level benefit by reducing transmission, in addition to the expected individual patient health gain through earlier diagnosis.

Little information was available on cost-effectiveness. One study using spot sputum screening calculated that ACF cost about US$1311 (£820) per case identified. A recent economic evaluation of the UK Find and Treat Service, which performs mobile X-ray screening in London, concluded that the ACF component was cost-effective at approximately US$28,766–35,156 (£18,000–22,000) per quality adjusted life year (QALY) gained.

The follow-up and treatment of homeless patients with TB can be difficult. Significant loss to follow-up has been shown in some programmes, usually between the point of referral for further investigation and subsequent diagnosis. An integrated service, bringing both comprehensive testing and treatment to the ‘street’, appeared to be more successful.

When screening was embedded within a TB clinic follow-up and the administration of care and DOT was optimised, a treatment completion rate of 89% was achieved among a population of illicit drug users and homeless people. Peer educators and community health workers, usually those who have had TB or the social risk factor, may also be able to play a role in improving success rates.

Nine studies described systematic ACF programmes in prisons. These initiatives were usually centrally organised case-finding exercises based on CXR or symptom questionnaires; most (8/9) had an LTBI screening component as well, predominantly in the USA. Seven of the studies describe screening as part of the medical assessment process on admission to prison; the other two were cross-sectional studies. Some countries have published guidance for screening in prisons, and there have been two audits of the effectiveness of implementing Centers for Disease Control and Prevention guidelines.

Where known (n = 5), the size of the screened population ranged between 702 and 209,076 prisoners (median 11,576), and between 1 and 218 TB cases (median 19) were detected (Appendix Table A.2B). For programmes where information was given or could be calculated (n = 5), the case yield ranged between 0.01% and 2.7%. An extensive European survey found that about 91% of the 22 responding countries performed TB screening on entry to prisons, mostly using CXR or sputum screening, with a yield of 0.39% (range 42–2362 cases). None of the studies contained information on cost-effectiveness.

Few studies describe ACF exclusively aimed at people with drug or alcohol problems, but there is a sizeable overlap with ACF in prisoners and homeless persons. A substantial proportion of those screened by the mobile X-ray initiatives described previously (Rotterdam, Paris and London) belong to these risk groups. One of the cross-sectional studies describing ACF focused on an opioid detoxification unit in an urban prison, and found 73 cases among the 1314 screened (5.6% yield). Another study described the successful use of financial incentives to improve the referral rate for CXR after LTBI screening.

Improving target group identification

The evidence reviewed in this article suggests that the case yield of ACF programmes is highly variable, not only between different risk groups, but also within similar risk groups and across roughly comparable outreach initiatives. This may be driven by differences in underlying risks (e.g., homelessness is a complex term that includes a wide variety of subgroups) and in the incidence of TB between the same risk groups in different countries. Consequently, any ACF programme in a low-incidence country should be informed by a needs assessment and robust surveillance.

It has been shown that clustering is higher among certain risk groups compared to other TB patients.
The evaluation of such evidence should form part of any needs assessment to determine which groups should be targeted. This is important because it is likely that transmission will vary according to the setting, the risk group and the virulence of certain *Mycobacterium tuberculosis* strain types. Molecular strain typing information of the TB isolate, using restriction fragment length polymorphism or mycobacterial interspersed repetitive units-variable number of tandem repeats, is now systematically collected in a number of low-incidence countries. It has been used to epidemiologically describe and investigate molecular clusters and, in some countries, produce national guidance documents for cluster investigation. While recent transmission cannot always be assumed within molecular clusters, these techniques have assisted outbreak investigations and the detection of transmission chains, where contact tracing procedures were good, however, this did not lead to the detection of many more additional cases. Given that the aim of ACF is to find PTB and hence prevent further transmission, knowledge about molecular clustering and transmission patterns may be useful to target interventions more effectively, and should be used to inform ACF among high-risk groups.

A further approach to targeting ACF activities is the use of geographic information systems (GIS). GIS mapping tools have been used to identify particular communities at higher risk of TB and may be combined with other sources of information, such as qualitative research tools and traditional epidemiology, to describe meeting places for some high-risk groups more accurately and target them more effectively.

**CONCLUSION**

There have been numerous successful ACF activities in countries with a low incidence of TB. Ideally, ACF should lead to both an impact on transmission and direct benefits for the individual patient through early detection. The effectiveness and, in some cases, cost-effectiveness of ACF among social risk groups, particularly the homeless, have been demonstrated, including evidence of transmission interruption. The evidence for screening of migrants depends on many factors, such as the screening setting and population, but overall it is less compelling, and further research is needed.

With low-incidence countries striving towards TB elimination, it may be necessary to improve the targeting of ACF campaigns. Collaboration with the voluntary sector and civil society is essential for case-finding interventions among hard-to-reach groups. New technologies, including molecular strain typing and/ or GIS, may provide useful information for targeting. In addition, tools for the detection and treatment of LTBI need to be improved. Inevitably, as successful TB control in low-incidence settings depends upon the global control effort, investment in international programmes in high-burden countries should remain a significant focus of low-incidence countries.

Case finding in low-incidence countries

**RÉSUMÉ**

Dans les pays à faible incidence, la tuberculose (TB) est largement concentrée dans des groupes de population à risque, tels que les migrants, les personnes sans domicile fixe, les usagers de drogues illicites, et les personnes alcoolodépendantes ou en prison. Cette situation a conduit à des efforts accrues pour mettre en place des dépistages actifs de cas de TB ciblés dans des populations spécifiques. Cette étude analyse les arguments scientifiques justifiant le dépistage actif chez les migrants et dans les groupes de population socialement à risque, ainsi que le rapport coût-efficacité des interventions.

Bien que les données provenant d'études d'observations soient en faveur de la recherche active de cas dans des groupes définis comme à haut risque, des études complémentaires sont nécessaires pour déterminer l'efficacité des outils spécifiques et le rapport coût-efficacité des stratégies de dépistage afin que les mesures de maîtrise de la TB dans les pays à faible incidence s'appuient sur des preuves scientifiques. La TB dans les pays à faible incidence dépendra inévitablement d'une maîtrise efficace de la maladie dans les pays à forte incidence.

**RESUMEN**

Hoy en día, en los países con baja incidencia, la tuberculosis (TB) se concentra en los grupos con alto riesgo de contraer la enfermedad como son los inmigrantes, las personas sin domicilio, los consumidores de drogas, los alcohólicos y la población de las prisiones. Esta situación ha dado lugar a una intensificación en la ejecución de las medidas de búsqueda activa de casos en poblaciones específicas. En el presente estudio se examinan los datos sobre la búsqueda activa de casos en las personas inmigrantes y en los grupos sociales de riesgo, además de la rentabilidad de las intervenciones. Los datos de los estudios observacionales respaldan la búsqueda de casos en los grupos específicos con alto riesgo de contraer la TB, pero se precisan nuevas investigaciones que determinen la eficacia de los instrumentos específicos de esta búsqueda y la rentabilidad de las estrategias de detección sistemática, con el propósito de documentar la elaboración de métodos de control basados en datos científicos y destinados a los países con baja incidencia. Es inevitable que la respuesta al problema de la TB en los países con baja incidencia dependerá de un control eficaz de la enfermedad en los países que presentan una alta carga de morbilidad.
